“Non-factorizable” terms in hadronic B-meson weak decays.

João M. Soares

TRIUMF, 4004 Wesbrook Mall, Vancouver, BC Canada V6T 2A3

Abstract

The branching ratios for the hadronic B-meson weak decays $B \rightarrow J/\psi K$ and $B \rightarrow D\pi$ are used to extract the size of the “non-factorizable” terms in the decay amplitudes. It is pointed out that the solutions are not uniquely determined. In the $B \rightarrow J/\psi K$ case, a 2-fold ambiguity can be removed by analyzing the contribution of this decay to $B \rightarrow Kl^+l^-$. In the $B \rightarrow D\pi$ case, a 4-fold ambiguity can only be removed if the “non-factorizable” terms are assumed to be a small correction to the vacuum insertion result.

1 Introduction

An increasing sample of B -mesons has been gathered from different experiments in recent times, and will tend to increase sharply in the near future with the advent of B -factories and, possibly, experiments in hadron colliders targeted at B -physics. The major concern in this paper is to clarify how such wealth of data can be used to study some of the aspects that remain unclear in the hadronic weak decays of the B and the other flavored mesons. The focus shall be on the 2-body decays that proceed through the tree level, Cabibbo favored, quark transitions $b \rightarrow c\bar{c}s$ and $b \rightarrow c\bar{u}d$. The corresponding effective weak Hamiltonian, once QCD corrections have been included, is the sum of two 4-quark operators, that only differ in the color indices of their quark fields and the strength of their Wilson coefficients. In the calculation of the decay amplitudes, one is faced with the task of evaluating the matrix elements, between the initial and final hadronic states, of those two 4-quark operators. The vacuum insertion (factorization) approximation [1] reduces this problem to that of determining the matrix elements of bilinear quark operators; such matrix elements can then be measured from leptonic and semi-leptonic decays, or calculated in some model for the mesons. Unfortunately, this is a poor approximation for one of the 4-quark operators: due to a mismatch in the color indices, its matrix element has significant “non-factorizable” terms [1], that do not appear in the vacuum insertion approximation. That these terms are important can be seen, for example, in the strong disagreement between the factorization predictions and the observed rates for the color suppressed B or D decays (see, for example, ref. [2]. In the color suppressed decays, the effect of the “non-factorizable” terms is enhanced by an accidental cancellation of the terms that are non-zero in the vacuum insertion approximation).

The standard procedure [2] in dealing with this discrepancy has been to preserve the vacuum insertion result for the hadronic matrix elements, but to replace the Wilson coefficients that multiply them by two free parameters. These parameters are then determined from a fit to the observed values of the branching ratios. For the case of the D - and B -meson decays, the two parameters (for each case) fit the available data quite well. For the D -mesons, the values of the parameters correspond to dropping the contribution of the color mismatched 4-quark operator altogether [2], which is a procedure that finds some theoretical justification in $1/N_c$ expansion arguments [3]. Quite

surprisingly, the recent data on B -meson decays has shown that, in this case, the values of the parameters do not obey the same rule [4]: neglecting the contribution of the color mismatched operator cannot be used as a systematic procedure to obtain the value of the free parameters, as it was the case for the D decays.

In view of the failure of the factorization approximation when applied to the color mismatched operator, and the failure of the standard procedure of dropping the contribution of that operator altogether, when applied to the B -meson decays, the “non-factorizable” terms have to be dealt with. Theoretical estimates, based on QCD sum rules, have been presented in refs. [5] and [6], for some decays. Here, I address the more basic question of extracting the size of the “non-factorizable” terms from the data. This program was first advocated by Deshpande, Gronau and Sutherland [7], and it has been recently applied to both D - and B -meson decays by Cheng [8]. In this work, I concentrate on the case of the B decays; where, except for the matrix elements of the operators with a color mismatch, the vacuum insertion approximation can be assumed to work well [9] (in particular, the effects of inelastic final state scatterings will be neglected for the B -decays considered in here). Special attention is paid to the ambiguities in the values of the “non-factorizable” terms that are extracted from the data. The results of Cheng [8] are recovered among other possible solutions. Finally, ways of lifting these ambiguities are discussed.

2 The “non-factorizable” terms in $B \rightarrow J/\psi K$ and $B \rightarrow D\pi$

The tree level, Cabibbo favored, hadronic weak decays of the B -mesons correspond to the quark transitions $b \rightarrow c\bar{c}s$ and $b \rightarrow c\bar{u}d$. The decay amplitudes are derived from the effective weak Hamiltonian

$$H_{eff} = \frac{G_F}{\sqrt{2}} [V_{cb}V_{cs}^*(C_1(\mu)\mathcal{O}_1^c + C_2(\mu)\mathcal{O}_2^c) + V_{cb}V_{ud}^*(C_1(\mu)\mathcal{O}_1^u + C_2(\mu)\mathcal{O}_2^u)], \quad (1)$$

where

$$\mathcal{O}_1^c = \bar{c}_\alpha \gamma^\mu (1 - \gamma_5) b_\alpha \bar{s}_\beta \gamma_\mu (1 - \gamma_5) c_\beta,$$

$$\mathcal{O}_2^c = \bar{s}_\alpha \gamma^\mu (1 - \gamma_5) b_\alpha \bar{c}_\beta \gamma_\mu (1 - \gamma_5) c_\beta, \quad (2)$$

and the operators $\mathcal{O}_{1,2}^u$ are obtained from $\mathcal{O}_{1,2}^c$, replacing $\bar{s}$ and c by $\bar{d}$ and u , respectively. The Wilson coefficients $C_1(\mu)$ and $C_2(\mu)$ contain the short distance QCD corrections. In the leading logarithm approximation, they are [10] $C_{1,2} = (C_+ \pm C_-)/2$, with

$$C_\pm(\mu) = \left(\frac{\alpha_s(\mu)}{\alpha_s(M_W)} \right)^{\frac{6\gamma_\pm}{33-2n_f}} \quad (3)$$

($\gamma_- = -2\gamma_+ = 2$; n_f is the number of active flavors). For $\Lambda_{\overline{MS}}^{(5)} = 200$ MeV [11], and at the scale $\mu = 5.0$ GeV, this gives

$$C_1 = 1.117 \quad C_2 = -0.266. \quad (4)$$

For the exclusive decays $B^- \rightarrow J/\psi K^-$ or $\bar{B}_d^0 \rightarrow J/\psi \bar{K}^0$, the amplitude is

$$\begin{aligned} A(B \rightarrow J/\psi K) &= \\ &= -\frac{G_F}{\sqrt{2}} V_{cb} V_{cs}^* (C_1 \langle J/\psi K | \mathcal{O}_1^c | B \rangle + C_2 \langle J/\psi K | \mathcal{O}_2^c | B \rangle). \end{aligned} \quad (5)$$

The hadronic matrix element of $\mathcal{O}_2^c$ is calculated in the vacuum insertion (factorization) approximation:

$$\langle J/\psi K | \mathcal{O}_2^c | B \rangle = \langle J/\psi | \bar{c}_\beta \gamma_\mu (1 - \gamma_5) c_\beta | 0 \rangle \langle K | \bar{s}_\alpha \gamma^\mu (1 - \gamma_5) b_\alpha | B \rangle. \quad (6)$$

Whereas, for $\mathcal{O}_1^c$, an additional “non-factorizable” term is included that reflects the color mismatch in the c - $\bar{c}$ quark fields:

$$\begin{aligned} \langle J/\psi K | \mathcal{O}_1^c | B \rangle &= \\ &= \frac{1}{N_c} \langle J/\psi | \bar{c}_\beta \gamma_\mu (1 - \gamma_5) c_\beta | 0 \rangle \langle K | \bar{s}_\alpha \gamma^\mu (1 - \gamma_5) b_\alpha | B \rangle \\ &+ \langle J/\psi K | \mathcal{O}_1^c | B \rangle_{non-fact.} \end{aligned} \quad (7)$$

The factor $1/N_c$ corresponds to the projection of the two color mismatched quark fields into a color singlet; it is included so that the “non-factorizable”

term (that is defined by eq. 7) vanishes in the vacuum insertion approximation. The decay amplitude can then be written as

$$A(B \rightarrow J/\psi K) = -\frac{G_F}{\sqrt{2}} V_{cb} V_{cs}^* M a, \quad (8)$$

with

$$a = C_2 + C_1 \left(\frac{1}{N_c} + X \right), \quad (9)$$

$$M \equiv \langle J/\psi | \bar{c}_\beta \gamma_\mu (1 - \gamma_5) c_\beta | 0 \rangle \langle K | \bar{s}_\alpha \gamma^\mu (1 - \gamma_5) b_\alpha | B \rangle \quad (10)$$

and

$$X \equiv \frac{1}{M} \langle J/\psi K | \mathcal{O}_1^c | B \rangle_{non-fact.} \quad (11)$$

In the BSW model [12], $M = 5.84 \text{ GeV}^3 \times f_\psi / (395 \text{ MeV})$. With $|V_{cb}| = 0.038 \sqrt{1.63 \text{ psec} / \tau_B}$ [13], and $f_\psi = 395 \text{ MeV}$ (which corresponds to $\Gamma(J/\psi \rightarrow e^+ e^-) = (5.26 \pm 0.37) \text{ keV}$ [11]), the branching ratio is

$$B(B \rightarrow J/\psi K) = 1.90 |a|^2 \%. \quad (12)$$

From the average of the experimental results [11]

$$\begin{aligned} B(B^- \rightarrow J/\psi K^-) &= (0.102 \pm 0.014) \% \\ B(\bar{B}^0 \rightarrow J/\psi \bar{K}^0) &= (0.075 \pm 0.021) \%, \end{aligned} \quad (13)$$

it follows that $|a| \simeq 0.22$, and so

$$X \simeq -0.29 \quad \text{or} \quad 0.10 \quad (14)$$

(the numerical differences with respect to the analogous results in ref. [8] correspond to the updated values of the parameters that were used in here). The 2-fold ambiguity in the value of X , which corresponds to the unknown sign of a , cannot be resolved by the branching ratio of $B \rightarrow J/\psi K$ alone.

Proceeding in a similar way for the exclusive processes $\bar{B}_d^0 \rightarrow D^+ \pi^-$, $\bar{B}_d^0 \rightarrow D^0 \pi^0$, and $B^- \rightarrow D^0 \pi^-$, the weak decay amplitudes are

$$\begin{aligned} A^{+-} &= -\frac{G_F}{\sqrt{2}} V_{cb} V_{ud}^* M_1 a_1, \\ A^{00} &= -\frac{G_F}{\sqrt{2}} V_{cb} V_{ud}^* \frac{1}{\sqrt{2}} M_2 a_2 \end{aligned}$$

and

$$A^{0-} = -\frac{G_F}{\sqrt{2}} V_{cb} V_{ud}^* M_1 a_1 [1 + \frac{M_2 a_2}{M_1 a_1}], \quad (15)$$

respectively (non-spectator contributions are very small and they have been neglected). The hadronic matrix elements M_1 and M_2 are

$$M_1 \equiv \langle D^+ | \bar{c}_\alpha \gamma^\mu (1 - \gamma_5) b_\alpha | \overline{B}_d^0 \rangle \langle \pi^- | \bar{d}_\beta \gamma_\mu (1 - \gamma_5) u_\beta | 0 \rangle \quad (16)$$

and

$$M_2 \equiv \sqrt{2} \langle \pi^0 | \bar{d}_\alpha \gamma^\mu (1 - \gamma_5) b_\alpha | \overline{B}_d^0 \rangle \langle D^0 | \bar{c}_\beta \gamma_\mu (1 - \gamma_5) u_\beta | 0 \rangle. \quad (17)$$

In the BSW model [12], $M_1 = 1.85 \text{ GeV}^3$ and $M_2 = 2.28 \text{ GeV}^3$ (for $f_D = 220 \text{ MeV}$). As in the previous case, the parameters

$$a_1 = C_1 + C_2 \left(\frac{1}{N_c} + X_1 \right) \quad (18)$$

and

$$a_2 = C_2 + C_1 \left(\frac{1}{N_c} + X_2 \right) \quad (19)$$

include the terms

$$\begin{aligned} X_1 &\equiv \frac{1}{M_1} \langle D^+ \pi^- | \mathcal{O}_2^u | \overline{B}_d^0 \rangle_{non-fact.} \\ X_2 &\equiv \frac{\sqrt{2}}{M_2} \langle D^0 \pi^0 | \mathcal{O}_1^u | \overline{B}_d^0 \rangle_{non-fact.}, \end{aligned} \quad (20)$$

where the “non-factorizable” matrix elements are defined by

$$\begin{aligned} \langle D^+ \pi^- | \mathcal{O}_2^u | \overline{B}_d^0 \rangle &= \frac{1}{N_c} M_1 + \langle D^+ \pi^- | \mathcal{O}_2^u | \overline{B}_d^0 \rangle_{non-fact.} \\ \sqrt{2} \langle D^0 \pi^0 | \mathcal{O}_1^u | \overline{B}_d^0 \rangle &= \frac{1}{N_c} M_2 + \sqrt{2} \langle D^0 \pi^0 | \mathcal{O}_1^u | \overline{B}_d^0 \rangle_{non-fact.}. \end{aligned} \quad (21)$$

In order to determine the values of the parameters a_1 and a_2 , the magnitudes of the decay amplitudes are extracted from the experimental value of the corresponding branching ratios [11],

$$\begin{aligned} B(\overline{B}_d^0 \rightarrow D^+ \pi^-) &= (0.30 \pm 0.04)\% \\ B(\overline{B}_d^0 \rightarrow D^0 \pi^0) &< 0.048\% \text{ (90\% C.L.)} \\ B(B^- \rightarrow D^0 \pi^-) &= (0.53 \pm 0.05)\%, \end{aligned} \quad (22)$$

and compared to the predictions in eq. 15. The later are the amplitudes in the absence of final state interaction effects, and so the comparison must be done with care (to be sure, I use the notation $\mathcal{A}^{+-}$, $\mathcal{A}^{00}$ and $\mathcal{A}^{0-}$ for the full amplitudes).

As for the $B \rightarrow J/\psi K$ case, it is assumed that the effects of inelastic final state interaction scatterings are negligible. However, the $B \rightarrow D\pi$ decays involve two isospin channels, and so an elastic final state interaction phase, δ , can appear between the two isospin amplitudes $A_{3/2}$ and $A_{1/2}$. In general,

$$\begin{aligned} A_{3/2} &= |A_{3/2}| \\ A_{1/2} &= |A_{1/2}|e^{i\delta'}, \end{aligned} \quad (23)$$

where $\delta' = \delta$ or $\delta + \pi$ (according to the relative sign of the two amplitudes in the absence of final state interactions). The full amplitudes $\mathcal{A}^{+-}$, $\mathcal{A}^{00}$ and $\mathcal{A}^{0-}$ are related to the isospin amplitudes $A_{3/2}$ and $A_{1/2}$, in the following way:

$$\begin{aligned} \mathcal{A}^{+-} &= \frac{1}{\sqrt{3}}A_{3/2} + \frac{\sqrt{2}}{\sqrt{3}}A_{1/2}, \\ \mathcal{A}^{00} &= \frac{\sqrt{2}}{\sqrt{3}}A_{3/2} - \frac{1}{\sqrt{3}}A_{1/2}, \\ \mathcal{A}^{0-} &= \sqrt{3}A_{3/2}. \end{aligned} \quad (24)$$

This allows to determine the magnitudes $|A_{1/2}|$ and $|A_{3/2}|$, as well as $\cos \delta'$, from the experimental results in eq. 22. In particular, it follows that

$$\cos \delta' > 0.77 \quad (25)$$

The lack of a more precise value for δ' is due to the fact that only an upper-limit exists for $B(\overline{B}_d^0 \rightarrow D^0\pi^0)$. For now, I will take $\delta' = 0$ (i.e. the final state interaction phase is either $\delta = 0$ or π). Then,

$$\begin{aligned} |A_{3/2}| &= \frac{1}{\sqrt{3}}|\mathcal{A}^{0-}| \\ |A_{1/2}| &= \frac{\sqrt{3}}{\sqrt{2}}(|\mathcal{A}^{+-}| - \frac{1}{3}|\mathcal{A}^{0-}|). \end{aligned} \quad (26)$$

Since the decay amplitudes in the absence of final state interactions are

$$\begin{aligned} A^{+-} &= \frac{1}{\sqrt{3}}|A_{3/2}| \pm \frac{\sqrt{2}}{\sqrt{3}}|A_{1/2}|, \\ A^{00} &= \frac{\sqrt{2}}{\sqrt{3}}|A_{3/2}| \mp \frac{1}{\sqrt{3}}|A_{1/2}|, \\ A^{0-} &= \sqrt{3}|A_{3/2}| \end{aligned} \quad (27)$$

(the two signs correspond to $\delta' = \delta$ or $\delta + \pi$), it follows that

$$|A^{+-}| = |\mathcal{A}^{+-}| \quad \frac{A^{0-}}{A^{+-}} = \frac{|\mathcal{A}^{0-}|}{|\mathcal{A}^{+-}|}, \quad (28)$$

for $\delta = 0$; and

$$|A^{+-}| = |\frac{2}{3}|\mathcal{A}^{0-}| - |\mathcal{A}^{+-}|| \quad \frac{A^{0-}}{A^{+-}} = \frac{|\mathcal{A}^{0-}|}{\frac{2}{3}|\mathcal{A}^{0-}| - |\mathcal{A}^{+-}|}, \quad (29)$$

for $\delta = \pi$. The predictions of eq. 15, in terms of the parameters a_1 and a_2 , are replaced on the LHS of these equations; whereas the experimental input from the branching ratios is used for the RHS. If the experimental result of eq. 25 is interpreted as showing a negligible phase shift from the final state interaction effects, eq. 28 gives (with $|V_{cb}|$ as before)

$$|a_1| \simeq 1.07 \quad 1 + 1.23 \frac{a_2}{a_1} \simeq 1.33; \quad (30)$$

and the size of the “non-factorizable” terms is then

$$X_1 \simeq -0.17 \quad X_2 \simeq 0.16 \quad (31)$$

or

$$X_1 \simeq 7.90 \quad X_2 \simeq -0.35 \quad (32)$$

(the positive value for X_2 corresponds to the result in ref. [8]). Alternatively, the data can be interpreted as showing a maximal phase shift. Then eq. 29 gives

$$|a_1| \simeq 0.12 \quad 1 + 1.23 \frac{a_2}{a_1} \simeq -11.63; \quad (33)$$

and so

$$X_1 \simeq 1.70 \quad X_2 \simeq -0.61 \quad (34)$$

or

$$X_1 \simeq 2.16 \quad X_2 \simeq 0.52. \quad (35)$$

The 4-fold ambiguity corresponds to the fact that the final state interaction phase can only be determined *modulo* π , and the sign of a_1 cannot be determined from the branching ratios in eq. 22.

At this point, a word should be said about the uncertainties in the results that were presented. The derivation of the parameters $|a|$, $|a_1|$ and $|a_2|$ suffers from the experimental errors in the branching ratios (in particular, $B(\overline{B}_d^0 \rightarrow D^0 \pi^0)$ is still missing), and in $|V_{cb}|$. These will improve with more accumulated data; which will also allow to derive the hadronic matrix elements of the bilinear quark operators from the semileptonic branching ratios (see the tests of factorization in ref. [4], for example). At present, the use of the BSW model [12] entails an uncertainty that is hard to quantify. The derivation of the terms X , X_1 and X_2 suffers from the additional uncertainty on the Wilson coefficients: in particular, the value chosen for the scale μ is important [14]. The positive solution for X and the negative solution for X_1 are the most sensitive as they involve somewhat delicate cancellations; for μ in the range 4.5 to 5.5 GeV, they oscillate by as much as 25% (whereas the other results vary by not more than 10%). I have taken $\mu = 5.0$ GeV, which is approximately the constituent b -quark mass.

It must be stressed that the vacuum insertion result has been assumed to work well for the operators with the correct color assignments (see for example eq. 6), and the inelastic final state scatterings have been deemed negligible. This is necessary in order to be able to derive the size of the “non-factorizable” terms from the data. In ref. [9], it is argued, on the basis of color transparency, that these assumptions are expected to hold for the low-multiplicity B decays. The argument is less reliable for the case of the D decays, and so they have not been considered in here.

3 Resolving the ambiguities

3.1 “Non-factorizable” terms in $B \rightarrow J/\psi K$

The sign of the parameter a , that appears in the $B \rightarrow J/\psi K$ amplitude of eq. 8, can be determined from the interference between the short distance contribution to $B \rightarrow Kl^+l^-$, and the long distance contribution due to $B \rightarrow KJ/\psi \rightarrow Kl^+l^-$. The short distance amplitude is derived from the effective weak Hamiltonian in eq. 1 (the operators $\mathcal{O}_{1,2}^c$ contribute at the 1-loop level), with the additional electroweak terms:

$$H'_{eff} = \frac{G_F}{\sqrt{2}} V_{tb} V_{ts}^* \sum_{i=7,8,9} C_i(\mu) \mathcal{O}_i, \quad (36)$$

where the operators

$$\begin{aligned} \mathcal{O}_7 &= \frac{e}{8\pi^2} m_b \bar{s}_\alpha \sigma^{\mu\nu} (1 + \gamma_5) b_\alpha F_{\mu\nu} \\ \mathcal{O}_8 &= \frac{\alpha}{2\pi} \bar{s}_\alpha \gamma^\mu (1 - \gamma_5) b_\alpha \bar{l} \gamma_\mu l \\ \mathcal{O}_9 &= \frac{\alpha}{2\pi} \bar{s}_\alpha \gamma^\mu (1 - \gamma_5) b_\alpha \bar{l} \gamma_\mu \gamma_5 l \end{aligned} \quad (37)$$

contribute to $B \rightarrow Kl^+l^-$ at tree level. For $m_t = 175$ GeV, the Wilson coefficients in eq. 36, in the leading logarithm approximation, are [17] $C_7 = 0.326$, $C_8 = -3.752$ and $C_9 = 4.581$. The decay amplitude is

$$\begin{aligned} A &= \frac{G_F \alpha}{\sqrt{2}\pi} V_{tb} V_{ts}^* [- \langle K | \bar{s} \gamma^\mu b | B \rangle \frac{1}{2} (C_{8eff} \bar{u}_l \gamma_\mu v_{\bar{l}} + C_9 \bar{u}_l \gamma_\mu \gamma_5 v_{\bar{l}}) \\ &\quad + \langle K | \bar{s} i \sigma^{\mu\nu} q_\nu (1 + \gamma_5) b | B \rangle C_7 m_b \frac{1}{q^2} \bar{u}_l \gamma_\mu v_{\bar{l}}] \end{aligned} \quad (38)$$

($q \equiv p_B - p_K$). The factor

$$C_{8eff} = C_8 - (3C_2 + C_1) g\left(\frac{4m_c^2}{q^2}, \frac{m_c^2}{m_b^2}\right) + 3ag_{LD} \quad (39)$$

includes the contribution

$$\begin{aligned} g(x, y) &= -\frac{4}{9} \ln y + \frac{4}{9} x + \frac{8}{27} - \frac{8}{9} \left(1 + \frac{1}{2}x\right) \sqrt{x-1} \arctan \frac{1}{\sqrt{x-1}} \theta(x-1) \\ &\quad - \frac{4}{9} \left(1 + \frac{1}{2}x\right) \sqrt{1-x} \left(\ln \frac{1 + \sqrt{1-x}}{1 - \sqrt{1-x}} + i\pi\right) \theta(1-x) \end{aligned} \quad (40)$$

from the operators $\mathcal{O}_{1,2}^c$, and the long distance contribution [18]

$$g_{LD} = \frac{3\pi}{\alpha^2} \sum_{V=J/\psi, \psi'} \frac{m_V \Gamma(V \rightarrow l^+ l^-)}{q^2 - m_V^2 + im_V \Gamma_V} \quad (41)$$

from the J/ψ and ψ' resonances. The parameter a that multiplies g_{LD} is the same as in eq. 8 (for simplicity, I have taken the same parameter for both the J/ψ and the ψ' resonances, but this is not necessary); the relative sign between the long distance and short distance contributions is well determined [19], up to the sign of a . The hadronic matrix elements are parameterized by

$$\begin{aligned} \langle K | \bar{s} \gamma^\mu b | B \rangle &= (p_B + p_K)^\mu f_+(q^2) + q^\mu f_-(q^2), \\ \langle K | \bar{s} i \sigma^{\mu\nu} (1 + \gamma_5) b | B \rangle &= s(q^2) [(p_B + p_K)^\mu q^\nu - (p_B + p_K)^\nu q^\mu \\ &\quad + i \epsilon_{\mu\nu\alpha\beta} (p_B + p_K)^\alpha q^\beta], \end{aligned} \quad (42)$$

where, in the static b -quark limit [20], $s = -(f_+ - f_-)/2m_B$. The modified BSW model [12] gives

$$\begin{aligned} f_+(q^2) &= \frac{h_0}{1 - \frac{q^2}{m_{0+}^2}} \frac{1}{1 - \frac{q^2}{(m_B + m_K)^2}}, \\ f_-(q^2) &= -f_+(q^2) \frac{m_B - m_K}{m_B + m_K}, \end{aligned} \quad (43)$$

with $h_0 = 0.379$ and $m_{0+} = 5.89$ GeV. The differential branching ratio is then

$$\begin{aligned} \frac{1}{\Gamma} \frac{d\Gamma}{dz} &= \frac{1}{48} \tau_B G_F^2 \alpha^2 |V_{tb} V_{ts}^*|^2 \left(\frac{m_B}{2\pi} \right)^5 (1 - z)^3 f_+^2 \\ &\quad \times (|C_9|^2 + |C_{8eff} + 2C_7|^2) \end{aligned} \quad (44)$$

($z \equiv q^2/m_B^2$), where the lepton and kaon masses were neglected. This is shown in fig. 1 for a positive and negative. Studying the region of the interference between the short and the long distance contributions will allow to determine the sign of a , and resolve the ambiguity in eq. 14. At present, the necessary sensitivity has not been reached yet, and only an upper limit exists on the non-resonant $B \rightarrow Kl^+ l^-$ decays [21].

3.2 “Non-factorizable” terms in $B \rightarrow D\pi$

The fortunate interference that allows to determine the sign of a is quite unique, and no similar effect appears for the decays of the type $b \rightarrow c\bar{u}d$, that would allow to determine the sign of a_1 in eq. 15. As for the final state interaction phase δ in eq. 23, it is known [22] that it should be the same phase that appears in D - π elastic scattering, at the energy $E_{c.m.} = m_B$. But this is of little use in determining its value. Indeed, it is hard to think of an experimental test that would lift the 4-fold ambiguity in the values of the two “non-factorizable” terms in the $B \rightarrow D\pi$ decays. On the other hand, it has been assumed throughout the analysis that the vacuum insertion result is a good approximation for the matrix elements of the operators with the correct color assignments. If it is further assumed that the vacuum insertion result should provide a first order approximation for the matrix elements of the color mismatched operators, then the X -terms should not be larger than unity. In particular, the solution for the $B \rightarrow D\pi$ decays is $X_1 \simeq -0.17$ and $X_2 \simeq 0.16$, as in eq. 31.

Although there is no reason to expect that this is so (the arguments in ref. [9], for example, cannot be extended to the case of the “non-factorizable” terms), it should be pointed out that the solutions with small X -terms tend to agree with the values predicted by the theoretical calculations that are presently available. Using QCD sum rules techniques, it has been predicted that $X_1 \simeq -0.33$ [5] (and, for the case of $B \rightarrow J/\psi K$, X is between -0.30 and -0.15 [6]). Similar results have been obtained for the “non-factorizable” term in the amplitude for $B^0 - \bar{B}^0$ mixing. The hadronic matrix element in the mixing amplitude is

$$M_{mix.} \equiv \langle B_q^0 | \bar{q}_\alpha \gamma^\mu (1 - \gamma_5) b_\alpha \bar{q}_\beta \gamma^\mu (1 - \gamma_5) b_\beta | \bar{B}_q^0 \rangle. \quad (45)$$

Proceeding in a similar way as for the decay amplitudes, a “non-factorizable” term is defined by

$$\begin{aligned} M_{mix.} &= 2(1 + \frac{1}{N_c}) m_B^2 f_B^2 \\ &+ \langle B_q^0 | \bar{q}_\alpha \gamma^\mu (1 - \gamma_5) b_\alpha \bar{q}_\beta \gamma^\mu (1 - \gamma_5) b_\beta | \bar{B}_q^0 \rangle_{non-fact.} \end{aligned} \quad (46)$$

(where $\langle B_q^0(p) | \bar{q} \gamma^\mu (1 - \gamma_5) b | 0 \rangle = -i f_B p^\mu$). The deviation from the vacuum insertion result (the first terms on the RHS of eq. 46) is parameterized by

the bag parameter B_B . Here,

$$B_B = 1 + \frac{1}{(1 + \frac{1}{N_c})} X_{mix.}, \quad (47)$$

where

$$X_{mix.} \equiv \frac{\langle B_q^0 | \bar{q}_\alpha \gamma^\mu (1 - \gamma_5) b_\alpha \bar{q}_\beta \gamma^\mu (1 - \gamma_5) b_\beta | \overline{B_q^0} \rangle_{non-fact.}}{2m_B^2 f_B^2}. \quad (48)$$

At present, the magnitude of B_B cannot be derived from the data on $B_d^0 - \overline{B_d^0}$ mixing, because one lacks a precise determination of f_B and of $|V_{td}|$ (for $B_s^0 - \overline{B_s^0}$ mixing, the CKM parameter is better known, but the strength of the mixing has not been determined experimentally). Using the lattice ($B_B = 1.2 \pm 0.2$) [23] and the QCD sum rules ($B_B = 1.0 \pm 0.15$) [24] estimates for the matrix element in the mixing, it follows that

$$0 \leq X_{mix.} \leq 0.53 \quad \text{and} \quad -0.2 \leq X_{mix.} \leq 0.2, \quad (49)$$

respectively.

4 Conclusion

The size of the “non-factorizable” terms in the amplitude for the decays $B \rightarrow J/\psi K$ and $B \rightarrow D\pi$ was derived from the experimental value of the corresponding branching ratios. The results can only be determined up to a discrete ambiguity. In the case of $B \rightarrow J/\psi K$, the 2-fold ambiguity can be lifted by determining the sign of the interference between the short distance contribution to $B \rightarrow Kl^+l^-$, and the long distance contribution due to $B \rightarrow KJ/\psi \rightarrow Kl^+l^-$. A similar ambiguity appears in the case of the $B \rightarrow D\pi$ decays; because the final state interaction elastic phase between the two isospin amplitudes can only be determined *modulo* π , the ambiguity becomes 4-fold. Contrary to the previous case, there is no simple way to determine the correct solution experimentally. However, all but one of the solutions indicates large “non-factorizable” terms that would indicate a breakdown of the vacuum insertion approximation when applied to the color mismatched operators. The analysis that was presented can be improved with future experimental results, in particular, with a measurement of the branching ratio

for $\overline{B}_d^0 \rightarrow D^0 \pi^0$. Also, other B -decays, similar to the ones shown in here, can be considered; the ambiguities in the values of the “non-factorizable” terms that are extracted from the data will appear in the same fashion.

I would like to thank A. Buras for a very useful discussion, and H.-Y. Cheng for carefully reading the manuscript and for his comments and corrections. This work was partly supported by the Natural Science and Engineering Research Council of Canada.

- [14] The strong μ dependence persists, when QCD corrections are included at the next-to-leading order [15] [16]. In ref. [15], it is shown that the higher order corrections must be included as part of a simultaneous expansion in $C_2 + C_1/N_c$ and α_s , to avoid unphysical results; no large deviation from the LLA result is apparent in the $B \rightarrow J/\psi + X_s$ decay. A different approach is advocated in ref. [16] for the exclusive decays. Using the NLO results in there would lead to a large renormalization scheme dependence in the “non-factorizable” terms.

Figure Caption

Figure 1: Differential branching ratio for $B \rightarrow Kl^+l^-$ ($z \equiv (p_B - p_K)^2/m_B^2$).
The full line corresponds to the long distance contribution alone,
whereas the other curves include the short distance contribution:
with $a > 0$ (dashed line) and $a < 0$ (dotted line).
